< 🗇 🕨

Triangular Matrices

- Matrix *L* is *lower triangular* if all entries above its main diagonal are zero, ℓ_{ij} = 0 for i < j
- Matrix U is upper triangular if all entries below its main diagonal are zero, u_{ij} = 0 for i > j
- Triangular matrices are important because triangular linear systems are easily solved by successive substitution
- Most direct methods for solving general linear systems first reduce matrix to triangular form and then solve resulting equivalent triangular system(s)
- Triangular systems are also frequently used as preconditioners in iterative methods for solving linear systems

Forward Substitution

For lower triangular system Lx = b, solution can be obtained by *forward substitution*

$$x_i = \left(b_i - \sum_{j=1}^{i-1} \ell_{ij} x_j\right) / \ell_{ii}, \quad i = 1, \dots, n$$

for
$$j = 1$$
 to n
 $x_j = b_j/\ell_{jj}$
for $i = j + 1$ to n
 $b_i = b_i - \ell_{ij}x_j$
end
end

{ compute soln component }

{ update right-hand side }

э

ヨト イヨト

Back Substitution

For upper triangular system Ux = b, solution can be obtained by *back substitution*

$$x_i = \left(b_i - \sum_{j=i+1}^n u_{ij} x_j\right) / u_{ii}, \quad i = n, \dots, 1$$

for
$$j = n$$
 to 1
 $x_j = b_j/u_{jj}$
for $i = 1$ to $j - 1$
 $b_i = b_i - u_{ij}x_j$
end
end

{ compute soln component }

< 🗇

{ update right-hand side }

э

Solving Triangular Systems

 Forward or back substitution requires about n²/2 multiplications and similar number of additions, so model serial time as

$$T_1 = t_c \, n^2/2$$

where t_c is cost of paired multiplication and addition (we ignore cost of n divisions)

 We will consider only lower triangular systems, as analogous algorithms for upper triangular systems are similar

Loop Orderings for Forward Substitution

for
$$j = 1$$
 to n
 $x_j = b_j/\ell_{jj}$
for $i = j + 1$ to n
 $b_i = b_i - \ell_{ij} x_j$
end
end

- right-looking
- immediate-update
- data-driven
- fan-out

for
$$i = 1$$
 to n
for $j = 1$ to $i - 1$
 $b_i = b_i - \ell_{ij} x_j$
end
 $x_i = b_i / \ell_{ii}$
end

- left-looking
- delayed-update
- demand-driven
- fan-in

Fine-Grain Algorithm 2-D Algorithm 1-D Column Algorithm 1-D Row Algorithm

Parallel Algorithm

Partition

- For i = 2, ..., n, j = 1, ..., i 1, fine-grain task (i, j) stores ℓ_{ij} and computes product $\ell_{ij} x_j$
- For i = 1, ..., n, fine-grain task (i, i) stores ℓ_{ii} and b_i , collects sum $t_i = \sum_{j=1}^{i-1} \ell_{ij} x_j$, and computes and stores $x_i = (b_i t_i)/\ell_{ii}$

yielding 2-D triangular array of $n\,(n+1)/2$ fine-grain tasks

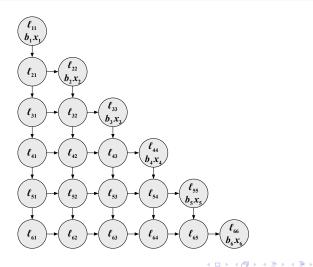

Communicate

- For j = 1, ..., n 1, task (j, j) broadcasts x_j to tasks (i, j), i = j + 1, ..., n
- For i = 2, ..., n, sum reduction of products $\ell_{ij} x_j$ across tasks (i, j), j = 1, ..., i, with task (i, i) as root

1-D Row Algorithm

Fine-Grain Tasks and Communication

ъ

Fine-Grain Algorithm 2-D Algorithm 1-D Column Algorithm 1-D Row Algorithm

Fine-Grain Parallel Algorithm

- if i = j then
 - t = 0
 - if i > 1 then

recv sum reduction of t across tasks $(i,k),\,k=1,\ldots,i$ end

$$x_i = (b_i - t)/\ell_{ii}$$

broadcast x_i to tasks (k, i), $k = i + 1, \ldots, n$

else

recv broadcast of x_j from task (j, j)

$$t = \ell_{ij} \, x_j$$

reduce t across tasks (i, k), $k = 1, \ldots, i$

end

イロト イポト イヨト イヨト

Fine-Grain Algorithm 2-D Algorithm 1-D Column Algorithm 1-D Row Algorithm

Fine-Grain Algorithm

- If communication is suitably pipelined, then fine-grain algorithm can achieve $\Theta(n)$ execution time, but uses $\Theta(n^2)$ tasks, so it is inefficient
- If there are multiple right-hand-side vectors *b*, then successive solutions can be pipelined to increase overall efficiency
- Agglomerating fine-grain tasks yields more reasonable number of tasks and improves ratio of computation to communication

Fine-Grain Algorithm 2-D Algorithm 1-D Column Algorithm 1-D Row Algorithm

Agglomeration

Agglomerate

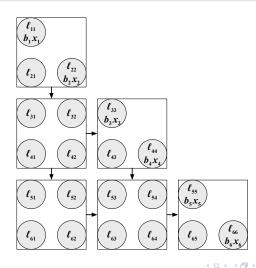

With $n \times n$ array of fine-grain tasks, natural strategies are

- 2-D: combine $k \times k$ subarray of fine-grain tasks to form each coarse-grain task, yielding $(n/k)^2$ coarse-grain tasks
- 1-D column: combine *n* fine-grain tasks in each column into coarse-grain task, yielding *n* coarse-grain tasks
- 1-D row: combine *n* fine-grain tasks in each row into coarse-grain task, yielding *n* coarse-grain tasks

Mapping

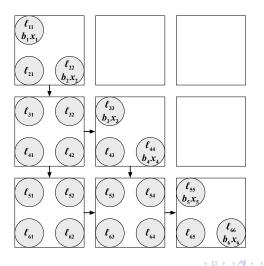

Мар

- 2-D: assign $(n/k)^2/p$ coarse-grain tasks to each of p processes using any desired mapping in each dimension, treating target network as 2-D mesh
- 1-D: assign n/p coarse-grain tasks to each of p processes using any desired mapping, treating target network as 1-D mesh

Fine-Grain Algorithm 2-D Algorithm 1-D Column Algorithm 1-D Row Algorithm

2-D Algorithm

- For 2-D agglomeration with $(n/\sqrt{p}) \times (n/\sqrt{p})$ subarray of fine-grain tasks per process, both vertical broadcasts and horizontal sum reductions are required to communicate solution components and accumulate inner products, respectively
- If each process holds contiguous block of rows and columns, we obtain block version of original fine-grain algorithm, with poor concurrency and efficiency
- Moreover, this approach yields only $(p + \sqrt{p})/2$ non-null processes, wasting almost half of 2-D mesh of processors

(日)

Fine-Grain Algorithm **2-D Algorithm** 1-D Column Algorithm 1-D Row Algorithm

2-D Algorithm

- Cyclic assignment of rows and columns to processes yields *p* non-null processes, so full 2-D mesh can be utilized
- But obvious implementation, looping over successive solution components and performing corresponding horizontal sum reductions and vertical broadcasts, still has limited concurrency because computation for each component involves only one process row and one process column
- Better algorithm can be obtained by computing solution components in groups of \sqrt{p} , which permits all processes to perform resulting updating concurrently

Fine-Grain Algorithm 2-D Algorithm 1-D Column Algorithm 1-D Row Algorithm

2-D Algorithm

Each step of resulting algorithm has four phases

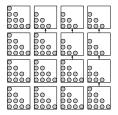

- Computation of next \sqrt{p} solution components by processes in lower triangle using 2-D fine-grain algorithm
- Broadcast of resulting solution components vertically from processes on diagonal to processes in upper triangle
- Computation of resulting updates (partial sums in inner products) by all processes
- Horizontal sum reduction from processes in upper triangle to processes on diagonal

< (**7**) →

1-D Column Wavefront Algorithm 1-D Row Wavefront Algorithm

Wavefront Algorithms

- Fan-out and fan-in algorithms derive their parallelism from inner loop, whose work is partitioned and distributed across processes, while outer loop is serial
- Conceptually, fan-out and fan-in algorithms work on only one component of solution at a time, though successive steps may be pipelined to some degree
- Wavefront algorithms exploit parallelism in outer loop explicitly by working on multiple components of solution simultaneously

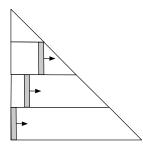

1-D Column Wavefront Algorithm 1-D Row Wavefront Algorithm

1-D Column Wavefront Algorithm

- 1-D column fan-out algorithm seems to admit no parallelism: after process owning column *j* computes *x_j*, resulting updating of right-hand side cannot be shared with other processes because they have no access to column *j*
- Instead of performing all such updates immediately, however, process owning column j could complete only first s components of update vector and forward them to process owning column j + 1 before continuing with next scomponents of update vector, etc.
- Upon receiving first s components of update vector, process owning column j + 1 can compute x_{j+1}, begin further updates, forward its own contributions to next process, etc.

1-D Column Wavefront Algorithm 1-D Row Wavefront Algorithm

1-D Column Wavefront Algorithm

To formalize wavefront column algorithm we introduce

- *z* : vector in which to accumulate updates to right-hand-side
- segment: set containing at most s consecutive components of z

1-D Column Wavefront Algorithm 1-D Row Wavefront Algorithm

1-D Column Wavefront Algorithm

for $j \in mycols$ for k = 1 to # segments recv segment if k = 1 then $x_i = (b_i - z_i)/\ell_{ii}$ $segment = segment - \{z_i\}$ end for $z_i \in segment$ $z_i = z_i + \ell_{ij} x_j$ end if |segment| > 0 then send *segment* to process owning column i + 1end end end イロト イポト イヨト イヨト

1-D Column Wavefront Algorithm 1-D Row Wavefront Algorithm

1-D Column Wavefront Algorithm

- Depending on segment size, column mapping, communication-to-computation speed ratio, etc., it may be possible for all processes to become busy simultaneously, each working on different component of solution
- Segment size is adjustable parameter that controls tradeoff between communication and concurrency
- "First" segment for given column shrinks by one element after each component of solution is computed, disappearing after *s* steps, when next segment becomes "first" segment, etc.

< 🗇 >

1-D Column Wavefront Algorithm 1-D Row Wavefront Algorithm

1-D Column Wavefront Algorithm

- At end of computation only one segment remains and it contains only one element
- Communication volume declines throughout algorithm
- As segment length s increases, communication start-up cost decreases but computation cost increases, and vice versa as segment length decreases
- Optimal choice of segment length *s* can be predicted from performance model

1-D Column Wavefront Algorithm 1-D Row Wavefront Algorithm

1-D Column Wavefront Algorithm

Approximate execution time is

$$T_p = ((t_s/s) + t_w + t_c) (n^2 + np + s(s-1)p^2)/(2p)$$

where s is segment length

• To determine isoefficiency function, set

$$t_c n^2/2 \approx E\left(\left((t_s/s) + t_w + t_c\right)(n^2 + np + s(s-1)p^2)/2\right)$$

which holds for large p if $n = \Theta(p)$, assuming s is constant, so isoefficiency function is $\Theta(p^2)$, since $T_1 = \Theta(n^2)$

1-D Column Wavefront Algorithm 1-D Row Wavefront Algorithm

1-D Row Wavefront Algorithm

- Wavefront approach can also be applied to 1-D row fan-in algorithm
- Computation of *i*th inner product cannot be shared because only one process has access to row *i* of matrix
- Thus, work on multiple components must be overlapped to attain any concurrency
- Analogous approach is to break solution vector x into segments that are pipelined through processes

1-D Column Wavefront Algorithm 1-D Row Wavefront Algorithm

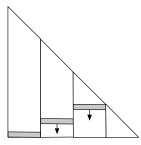

1-D Row Wavefront Algorithm

- Initially, process owning row 1 computes x_1 and sends it to process owning row 2, which computes resulting update and then x_2
- This process continues (serially at this early stage) until *s* components of solution have been computed
- Henceforth, receiving processes forward any full-size segments before they are used in updating
- Forwarding of currently incomplete segment is delayed until next component of solution is computed and appended to it

< 🗇 🕨

1-D Column Wavefront Algorithm 1-D Row Wavefront Algorithm

1-D Row Wavefront Algorithm

```
for i \in myrows
   for k = 1 to # segments -1
       recv segment
       send segment to process owning row i + 1
       for x_i \in segment
           b_i = b_i - \ell_{ii} x_i
       end
   end
   recv segment /* last may be empty */
   for x_i \in segment
       b_i = b_i - \ell_{ii} x_i
   end
   x_i = b_i / \ell_{ii}
   segment = segment \cup \{x_i\}
   send segment to process owning row i + 1
end
```

1-D Column Wavefront Algorithm 1-D Row Wavefront Algorithm

1-D Row Wavefront Algorithm

- Instead of starting with full set of segments that shrink and eventually disappear, segments appear and grow until there is a full set of them
- It may be possible for all processes to be busy simultaneously, each working on different segment
- Segment size is adjustable parameter that controls tradeoff between communication and concurrency, and optimal value of segment length s can be predicted from performance model
- Performance analysis and resulting performance model are more complicated than for 1-D column wavefront algorithm, but performance and scalability for 1-D row wavefront algorithm are nevertheless similar

1-D Column Cyclic Algorithm 1-D Row Cyclic Algorithm

Cyclic Algorithms

- In wavefront algorithms, each segment is sent up to s times and may pass through same process repeatedly, depending on mapping of rows or columns
- Cyclic algorithms are somewhat similar to wavefront algorithms, but they minimize communication by exploiting cyclic mapping of rows or columns
- Instead of having variable number of segments of adjustable length, cyclic algorithms circulate single segment of length p-1

< 17 ▶

1-D Column Cyclic Algorithm 1-D Row Cyclic Algorithm

1-D Column Cyclic Algorithm

- In cyclic 1-D column algorithm, segment of size p 1, containing partially accumulated components of update vector z, passes from process to process, one step for each column of matrix, cycling through all p - 1 other processes before returning to any given process
- At step *j*, process owning column *j* receives segment from process owning column *j* - 1 and uses its first element (which has accumulated all necessary prior updates) to compute *x_j*
- Task owning column *j* then modifies segment by deleting first element, updating remaining elements, and appending new element to begin accumulation of *z*_{j+p-1}

1-D Column Cyclic Algorithm 1-D Row Cyclic Algorithm

1-D Column Cyclic Algorithm

- Segment is then sent to process owning column *j* + 1, where similar procedure is repeated
- After forwarding modified segment, process owning column *j* then computes remaining updates resulting from *x_j*, which will be needed when segment returns to this process again
- Updating while segment is elsewhere provides all concurrency, since computations on segment are serial

< 🗇 🕨

1-D Column Cyclic Algorithm 1-D Row Cyclic Algorithm

1-D Column Cyclic Algorithm

for $j \in mycols$ recv segment $x_i = (b_i - z_i - t_i)/\ell_{ii}$ segment = segment - $\{z_i\}$ for $z_i \in segment$ $z_i = z_i + t_i + \ell_{ij} x_j$ end $z_{i+p-1} = t_{i+p-1} + \ell_{i+p-1,i} x_i$ segment = segment $\cup \{z_{i+n-1}\}$ send *segment* to process owning column j + 1for i = i + p to n $t_i = t_i + \ell_{ij} x_j$ end end

1-D Column Cyclic Algorithm 1-D Row Cyclic Algorithm

1-D Column Cyclic Algorithm

- Segment must pass through *all* other processes before returning to any given process, so correctness depends on use of cyclic mapping
- Maps naturally to 1-D torus (ring) network, but since only one pair of processes communicates at any given time, also works well with bus network
- Attains minimum possible volume of interprocessor communication to solve triangular system using column-oriented algorithm

1-D Column Cyclic Algorithm 1-D Row Cyclic Algorithm

1-D Column Cyclic Algorithm

• For $n \leq p (t_p + p)$, where

$$t_p = (t_s + t_w(p-1))/t_c$$

is cost, measured in flops, of sending message of length p-1, execution time is determined by segment cycle time, so that

$$T_p = t_c(n(t_p + p) - p(p-1)/2 - t_p)$$

 For n > p (t_p + p), execution time is dominated by cost of updating, so that

$$T_p = t_c((n^2 + np)/(2p) + p((t_p + p)^2 - t_p - p + 1)/2 - t_p)$$

1-D Column Cyclic Algorithm 1-D Row Cyclic Algorithm

1-D Column Cyclic Algorithm

- Two-phase behavior complicates scalability analysis, but tradeoff point between phases for n as function of p grows like p^2 , so isoefficiency function is at least $\Theta(p^4)$
- Performance of both phases can be improved
 - Segment cycle time can be reduced by breaking segment into smaller pieces and pipelining them through processes
 - Updating work can be reorganized, deferring excessive work until later cycles, to obtain more even distribution throughout computation

< 🗇 🕨 🔸

1-D Column Cyclic Algorithm 1-D Row Cyclic Algorithm

1-D Row Cyclic Algorithm

- 1-D row cyclic algorithm is similar, except processes are agglomerated by rows and segment contains p-1 components of solution x
- At step *i*, process owning row *i* receives segment from process owning row *i* - 1 and uses components of *x* it contains to complete *i*th inner product, so that *x_i* can then be computed
- Task then modifies segment by deleting first element and appending new element *x_i* just computed
- Segment is then sent to process owning row *i* + 1, where similar procedure is repeated

1-D Column Cyclic Algorithm 1-D Row Cyclic Algorithm

1-D Row Cyclic Algorithm

- After forwarding modified segment, process then computes partial inner products that use components of segment, which will be further accumulated when segment returns to this process again
- Latter computations, which take place while segment passes through other processes, provide concurrency in algorithm, because computations on segment itself are serial
- Again, correctness of algorithm depends on use of cyclic mapping
- Performance and scalability are similar to those for 1-D column cyclic algorithm, although details differ

1-D Column Cyclic Algorithm 1-D Row Cyclic Algorithm

1-D Row Cyclic Algorithm

for $i \in myrows$ recv segment for $x_i \in segment$ $b_i = b_i - \ell_{ij} x_j$ end $x_i = b_i / \ell_{ii}$ segment = segment - $\{x_{i-p}\} \cup \{x_i\}$ send *segment* to process owning row i + 1for $m \in myrows, m > i$, for $x_i \in segment$ $b_m = b_m - \ell_{mi} x_i$ end end end
