# **Introduction to MATLAB**

#### **Basics**

MATLAB is a high-level interpreted language, and uses a "read-evaluate-print" loop: it *reads* your command, *evaluates* it, then *prints* the answer. This means it works a lot like a calculator:

```
>> 1+2
ans = 3
```

Here, it read the command 1+2, evaluated it to 3 and printed that. It also stores the answer from that in the variable ans so that you can refer to it in the next command if you want.

```
>> 1.5^2 + 2.5^2
ans =
    8.5000
>> sqrt(ans)
ans =
    2.9155
```

Be careful: after executing the second line, ans now has a new value. This also shows the syntax for a power ( $a^b$  is evaluated using a^b) and square root using the sqrt function. Much of the syntax follows mathematical syntax that you would expect, such as cos (angle) to get the cosine of an angle, for example.

You can create your own variables, and assign them values using =

All of your current variables, and their values, are listed in the **workspace** on the right hand side. If you want to clear out all of the variables, use clear.

If you want to change how many digits are output, or use scientific notation automatically, use the format command. The default is format short, and format shortEng will use engineering notation (scientific notation, where the exponent on 10 is a factor of 3). You can also use format long and format longEng.

### **Useful functions**

The trigonometric functions are all at your disposal: cos, sin, tan, and their inverses acos, asin, and atan. There is also atan2(y,x) which takes two values, y and x being the height and base of a triangle (rather than atan(y/x)). That version gives you the angle in the correct quadrant. All of the trigonometric functions use radians; if you want to give an argument in *degrees*, then use cosd, sind, tand, and so on.

```
>> atan2(1,1)
ans =
      0.7854
>> atan2d(1,1)
ans =
      45
```

You can also convert between radians and degrees using deg2rad and rad2deg. Finally, you can access the value of  $\pi$  by using pi. *Be careful:* MATLAB allows you to use pi as a variable name, which . . . could give you surprising results if you, e.g., pi = 3.

## **Keyboard shortcuts**

**Help.** If you're not sure what a command does, type help *commandname*. If you can't remember if cos uses radians or degrees, then help cos will tell you. You can also search the documentation in the upper right hand corner.

**Tab completion.** If you're typing a command like cos, when you hit the TAB key, it will give you a list of commands that start with the letters cos.

**Command history.** You can use the up and down arrows to move through previous commands that you've entered. You can then press ENTER to rerun that command exactly, or move the cursor left and right in the line and make edits (e.g., if you made a mistake you need to correct). This is useful if you've made an error with a variable value and need to reevaluate an expression.

### **Vectors and matrices**

MATLAB (MATrix LABoratory) is optimized for working with *vectors* and *matrices*. As such, it has a nice syntax for making vectors and matrices easily, using the [] syntax

You can separate entries in a vector using a space or a comma (and can mix and match: [1 2,3]), and you separate the rows in a matrix using a semicolon.

You can then access the values inside a vector  $(v_i)$  or matrix  $(M_{ij})$  with ()

The indices follow row-column order, so that  $M_{ij}$  is M (i, j), and the indices begin at 1. In addition to accessing entries, you can also assign values.

>> 
$$M(2,1) = 10$$
  
 $M = 5$   
 $10$   
 $8$ 

If you want a row or column vector out of a matrix, you use the : operator; then M(1, :) gives you the row  $M_{1j}$ , while M(:, 1) gives you the column  $M_{i1}$ .

You can do things like get the dot product of  $\vec{a}$  and  $\vec{b}$  with dot (a,b); you can get the crossproduct  $\vec{a} \times \vec{b}$  with cross (a,b). You can get the transpose of a vector or matrix with the 'operator

*Note:* the transpose of a *row vector* (like  $[1 \ 2]$ ) is a *column vector* (like [1;2]). To right-multiply a vector times a matrix (like  $M \cdot \vec{v}$ ), the vector needs to be a column vector. You can also use this to take dot-products if you want: if A and B are row vectors, then dot (A, B) is the same as A\*B'.

For a matrix, you can access the determinant with det(M) and the trace (sum along the diagonal) with trace (M)

The eigenvalues and eigenvectors of a matrix can be computed using eig

```
>> Msq = [1 0.5 0.25 ; 0.5 -1 0.75 ; 0.25 0.75 0]
Msq =
    1.0000
              0.5000
                         0.2500
                         0.7500
    0.5000
             -1.0000
    0.2500
              0.7500
                               0
>> eig(Msq)
ans =
   -1.4461
    0.1693
    1.2768
```

```
>> [V,D] = eig(Msq)
V =
    0.1370
              -0.4514
                         -0.8817
   -0.8888
              0.3369
                         -0.3106
    0.4373
               0.8262
                         -0.3551
D =
   -1.4461
                                0
                     0
                                0
          0
               0.1693
          \Omega
                          1.2768
```

The first form, eig (M) just gives a vector listing the eigenvalues. The second, [V, D] = eig(M), returns the eigenvalues in a diagonal matrix D (and you can get those entries using diag(D)), and the eigenvectors are the columns of V. Thus, the first eigenvector is V(:, 1) and has eigenvalues D(1, 1); the second is V(:, 2) with eigenvalue D(2, 2), and the third is V(:, 3) with eigenvalue D(3, 3).

### **Solving (linear) equations**

We can use MATLAB to solve equations, including systems of equations. For our purposes, we will almost exclusively deal with linear equations. The first step is defining a set of *symbolic variables* using syms

```
>> syms Fx Fy Fz
```

With these, we can construct vectors of symbolic variables, including more complicated expressions

```
>> F = [Fx Fy Fz]
F =
[Fx, Fy, Fz]
```

but you could also have F1 = [Fx, -2\*Fy, 3+Fz] as a valid expression, and you can mix and match with numeric vectors; so you can make the combination F + [0 0 -900] if you wanted to add the force F to a force  $-900\hat{k}$ .

From these expressions, we can either use solve or linsolve. The syntax is very similar, though each are slightly idiosyncratic. First, solve for a series of equations using == to indicate *equality* instead of *assignment* 

```
>> struct2array(solve([ F == [0 \ 0 \ -900] ], [Fx Fy Fz])) ans = [0, 0, -900]
```

The solve ([ equations ], [ variables ]) returns an object that contains symbolic solutions, while struct2array converts it into an array. Note: the symbolic expressions may be returned as fractions, and so you will need to use double() to convert the fraction into a floating point number. You can use double(ans) to convert the entire vector answer if you would like.

You can use more complicated expressions in your solve; for example, we use cross to get cross-products for moments. You can set an entire vector to zero by writing F = 0.

Alternatively, you can convert your linear problem to matrix form Av = b and use linsolve

### **Numerical integration**

MATLAB has the ability to integrate in one, two, or even three dimensions. However, you need to understand *anonymous functions* (a function that you cook up without giving it a name), and how to deal with some vector operations.

**Anonymous functions.** There are two places where we may deal with anonymous functions: the integrand, and the limits of an integral. For example,

$$\int_0^\pi \cos^2 x \sin^2 x \ dx$$

we'll need to be able to define the function  $\cos^2 x \sin^2 x$ . Another example, if we integrate

$$\int_{-R}^{R} dx \int_{-\sqrt{R^2 - x^2}}^{\sqrt{R^2 - x^2}} y^2 dy$$

then we will also want to define the functions  $-\sqrt{R^2-x^2}$  and  $\sqrt{R^2-x^2}$  which define the lower and upper bounds of integration for y. We do this by using the @ operator. For example, the first case would be @ (x) (cos(x)).^2 .\* (sin(x)).^2. The first part, @ (x), tells us its a function of one variable x, and the rest, (cos(x)).^2 .\* (sin(x)).^2, is the expression to evaluate given x. So if we want to evaluate that integral, we'd do

```
>> integral(@(x) (cos(x)).^2 .* (sin(x)).^2, 0, pi) ans = 0.3927
```

This also shows how integral works: it takes a function, and integrates it over a range. You can use Inf (or -Inf) to get  $\infty$  (or  $-\infty$ ) as an endpoint on the range, too. For our second example it's a bit longer:

The two-dimensional integral 2 takes in  $x_{\min}$ ,  $x_{\max}$ ,  $y_{\min}$ , and  $y_{\max}$  where the y limits can be functions of x. You'll also notice that integral 2 takes in a function of two variables now: x and y.

You can, if you wish, name your anonymous function:

```
>> fupper = @(x) sqrt(R.^2-x.^2)
fupper =
     @(x) sqrt(R.^2-x.^2)
>> fupper(0)
ans =
     1
```

you can then also pass them to functions like integral:

```
>> flower = @(x) -sqrt(R.^2-x.^2)
flower =
    @(x)-sqrt(R.^2-x.^2)
>> integral2(@(x,y) y.^2, -R, R, flower, fupper)
ans =
    0.7854
```

**Vector operations.** You probably noticed that we used .  $\hat{}$  to raise to the second power, rather than  $\hat{}$  and .\* to do multiplication rather than \*. This may look odd, but the reason is that integral (or integral2) is going to construct a *vector* of x values and call the integrand for the entire *vector*; it expects to get back a *vector* of answers. This is to make the evaluation of integral efficient: it finds a grid of x (or x and y values for integral2) and then passes them to the function. So we need to be able to call our functions like

>> fupper(
$$[-1, -0.5, 0, 0.5, 1]$$
)
ans =

0 0.8660 1.0000 0.8660 0

and get a vector back. But if you try to use ^, you'll get

```
>> [-1, -0.5, 0, 0.5, 1]^2
Error using ^
Inputs must be a scalar and a square matrix.
To compute elementwise POWER, use POWER (.^) instead.
```

which is fixed like this

>> 
$$[-1, -0.5, 0, 0.5, 1].^2$$
  
ans =  
 $1.0000 0.2500 0 0.2500 1.0000$ 

So: using .^ tells MATLAB to apply ^ to each element in the vector or matrix individually. Similarly, you use .\* to do an element-by-element multiplication. Many built-in functions, like cos, sin, exp, sqrt and so on *already work on vectors element-by-element*, so there's nothing you have to do differently.

Finally, this leads to probably *the most confusing* piece of MATLAB code you will encounter. Suppose you wanted to integrate an *area* 

$$\int_{-R}^{R} dx \int_{-\sqrt{R^2 - x^2}}^{\sqrt{R^2 - x^2}} dy$$

(the area of a circle of radius R in this case). The integrand would be 1, so it would seem like you could just do

The reason is that 1 is *not* an array of the same size as the array of x and y values that were passed. So you need to do something a little different:

Q = integral2Calc(fun,xmin,xmax,yminfun,ymaxfun,opstruct);

```
>> integral2(@(x,y) ones(size(x)), -R, R, @(x) -sqrt(R.^2-x.^2), ...
@(x) sqrt(R.^2-x.^2))
ans =
3.1416
```

The function ones returns an array of 1's of a given size, and size(x) finds the size of the input array x. It looks a little odd, but it does what you need.

An alternative approach is to use arrayfun (see below information about plotting), but you may find that more unwieldy than helpful.

### **Creating new functions**

You can define a function in an individual file, so that you can call it just like a built-in MATLAB function. Clicking on the Editor tab at the top of Matlab, press the + button to create a new blank file, or select the option New Function from the menu under +. The syntax for a function is

```
function <output> = name(<input>)
%comments go after percent signs
%more function here
...
end
```

When you save the file as <name>.m, name will be the function name. Make sure to save it in the folder you're currently working in, and then you can call the function as

```
>> name(<input>)
```

As a concrete example to see how this works, we'll make two functions: one to compute the area of a rectangle, and the second the area of a right triangle—each will have it's own file. First,

```
function A = rectanglearea(width, height)
%rectanglearea returns area of rectangle given width and height
A = width*height;
end
```

**Note:** the value that is returned from rectanglearea is whatever value is in the variable A when the end is reached. That's what the A = rectanglearea means. Note also that we use; to end each line—this tells MATLAB not to output the result of the steps as it executes them. We can also add in simple error checks if we want:

```
function A = rectanglearea(width, height)
%rectanglearea returns area of rectangle given width and height
if (width < 0) | (height < 0)
    error('Width and height must both be non-negative')
end
A = width*height;
end</pre>
```

The pipe | means "logical or" (and & means "logical and"); 'error' returns an error message. After we save the file rectanglearea.m, we can call the function

```
>> rectanglearea(2,4)
ans =
    8
```

We can also have functions that call our new functions, so

```
function A = trianglearea( base, height )
%trianglearea returns area of triangle given base and height
A = 0.5*rectanglearea(base, height);
end
```

can be saved in trianglearea.m and then call the function

```
>> trianglearea(2,4)
ans =
4
```

so long as rectanglearea.m is also in the correct folder. Note also that inside of a function, you can create "temporary" variables that you may need for the calculation. For example,

```
function A = circlearea( radius )
%circlearea returns area of a circle with radius
if radius < 0
        error('Radius must be positive.')
end
yupper = @(x) sqrt(radius^2 - x.^2);
ylower = @(x) -yupper(x);
A = integral2(@(x,y) ones(size(x)), -radius, radius, ylower, yupper);
end</pre>
```

### and then

```
>> circlearea(1.)
ans =
3.1416
```

But you will notice, if you run this, that yupper and ylower are not listed in the workspace—they only exist "inside" circlearea.

### Plotting (and arrayfun)

MATLAB will let you plot a *vector* of y values against x values. So you could do

```
>> plot([0, 1, 2, 3], [0, 1, 4, 9])
```

and MATLAB would show you those four points corresponding to  $y=x^2$ . But to make this more automated, you will want to create the vector X corresponding to equally spaced values; the : operator let's you do this:

```
>> 1:5
ans =
    1    2    3    4    5
>> -3:3
ans =
```

```
-3 -2 -1 0 1 2 3

>> -1:0.5:1

ans =
    -1.0000 -0.5000 0 0.5000 1.0000
```

So *start*: *finish* returns a vector from *start* to *finish* in steps of 1, and *start*: *step*: *finish* uses *step* as the step size. So, let's do

```
>> X = -3:0.1:3;
```

to get our x values. Next, we'll want to make our y vector, and plot; that can be done using

```
>> Y = X.^2;
>> plot(X,Y)
```

If we want to plot a more complicated function, like circlearea, we need to construct the array of values; that is what arrayfun does:

```
>> R = 0:0.1:5;
>> A = arrayfun(@circlearea, R);
>> plot(R,A)
```

In this case, arrayfun applies the function circlearea to each value in the vector R. **Note:** the @ is needed if the function (circlearea in this case) is defined in a file. If we had a function that took two variables, like rectanglearea, we could do

```
>> W = 1:5; H = 2:6;
>> A = arrayfun(@rectanglearea, W, H);
>> A
A =
2 6 12 20 30
```

Finally, there are lots of options to control how the plot appears. To make red circles, you do

```
>> plot(X,Y,'ro')
```

See this link for a complete list of plot line specifications, or read the help under plot.

You can also define title, and x and y axis labels:

```
>> title('a title')
>> xlabel('x axis label')
>> ylabel('y axis label')
```

Note that as you enter each command, the graph in your plot window will reflect your change. You can also plot two functions at once:

```
>> X = -3:0.1:3;
>> Y1 = X.^2;
>> Y2 = X.^3;
>> plot(X,Y1, X,Y2)
```

You may also add line specifications to each curve.
